

# Tests from 10-27-2017: Finding Encoder Velocity Issues

## Test Setup

All tests done with an unloaded 50:1 motor. With the following gains:

- Velocity gains:
  - P:  $100 * 2^{12}$ ,
  - I:  $512 * 2^{12}$
- Current gains (N/A for no current):
  - P:  $32 * 2^{12}$ ,
  - I:  $640 * 2^{12}$

Most of the tests are run with the:

- w/ current firmware (r141)
- w/o current firmware (no\_current\_test\_001)

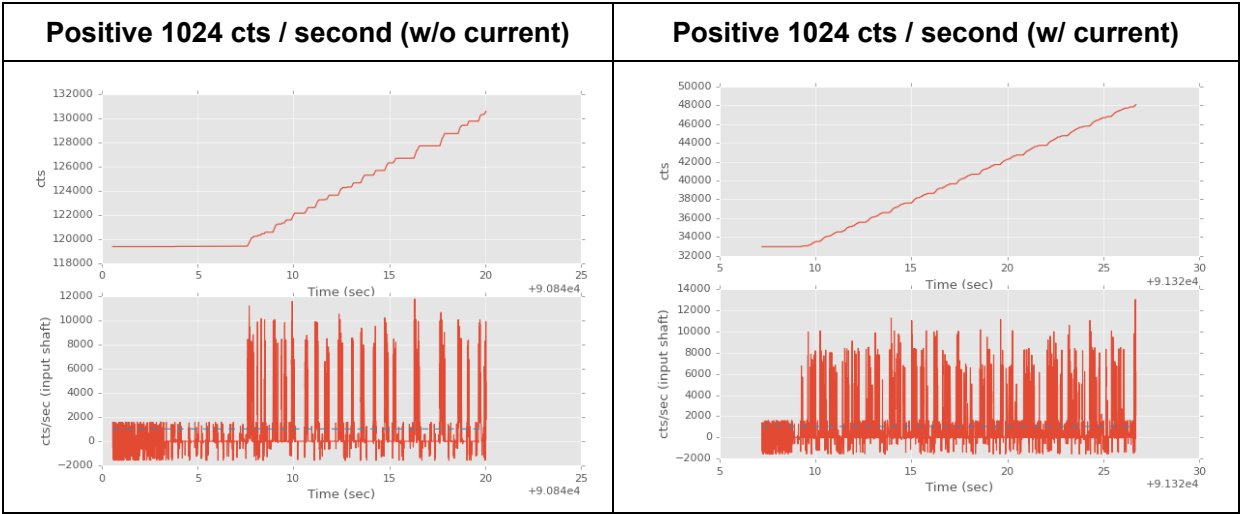

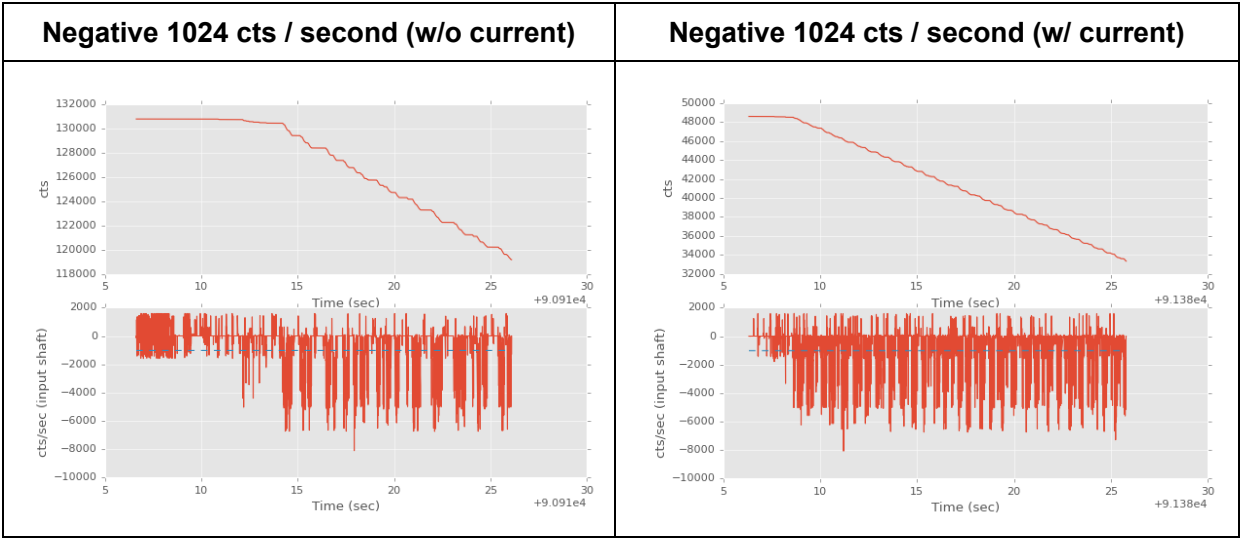

In all graphs the blue dotted line is the target velocity, the top graph is position and the bottom graph is velocity. (as the units indicate).

All data was taken over canopen with a sync period of .004.

## Test Results

First I ran the motor at 1024 cts/second (one revolution per second at the input shaft). The results are similar for positive and negative rotation.

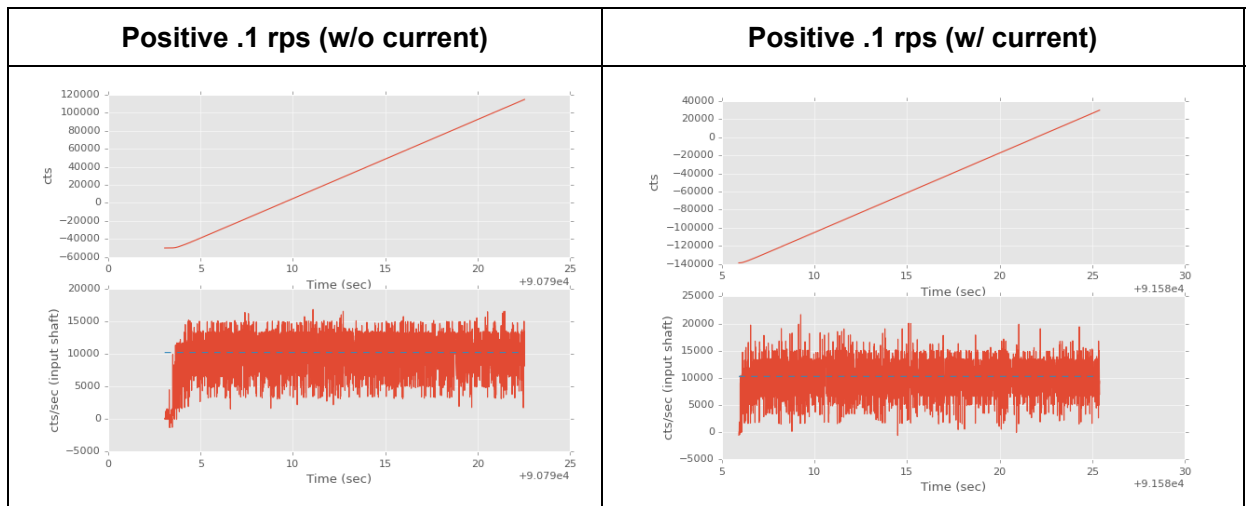

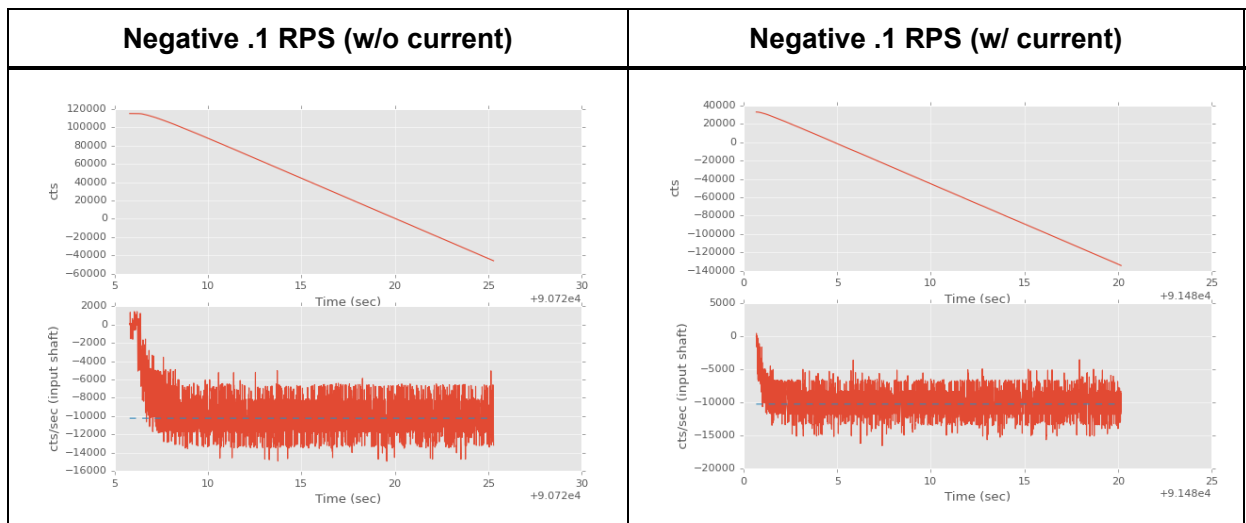

I then doubled the speed with similar results.

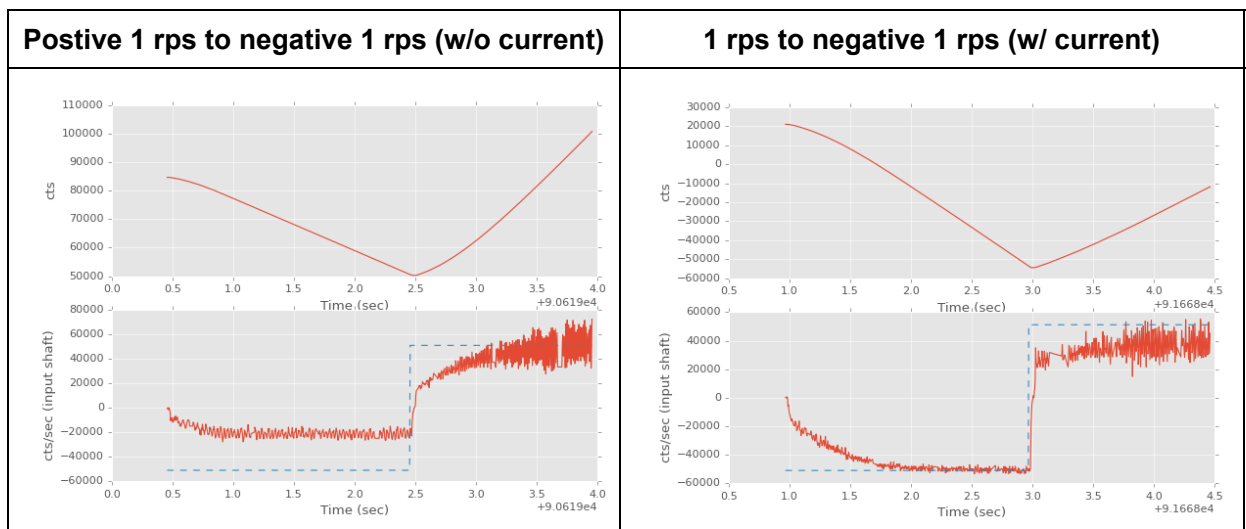

At around 10x1024 cts / second (.2 Rotations / Second at the output shaft) the erratic motion is less noticeable, but the velocity noise is still high.

At around 50x1024 cts / second (1 rotation / second at the output shaft) the erratic motion was not present, but some assymetry between the positive and negative going signals was. This is worse without current, but this may be due to incorrec tuning parameters somewhere along the way.

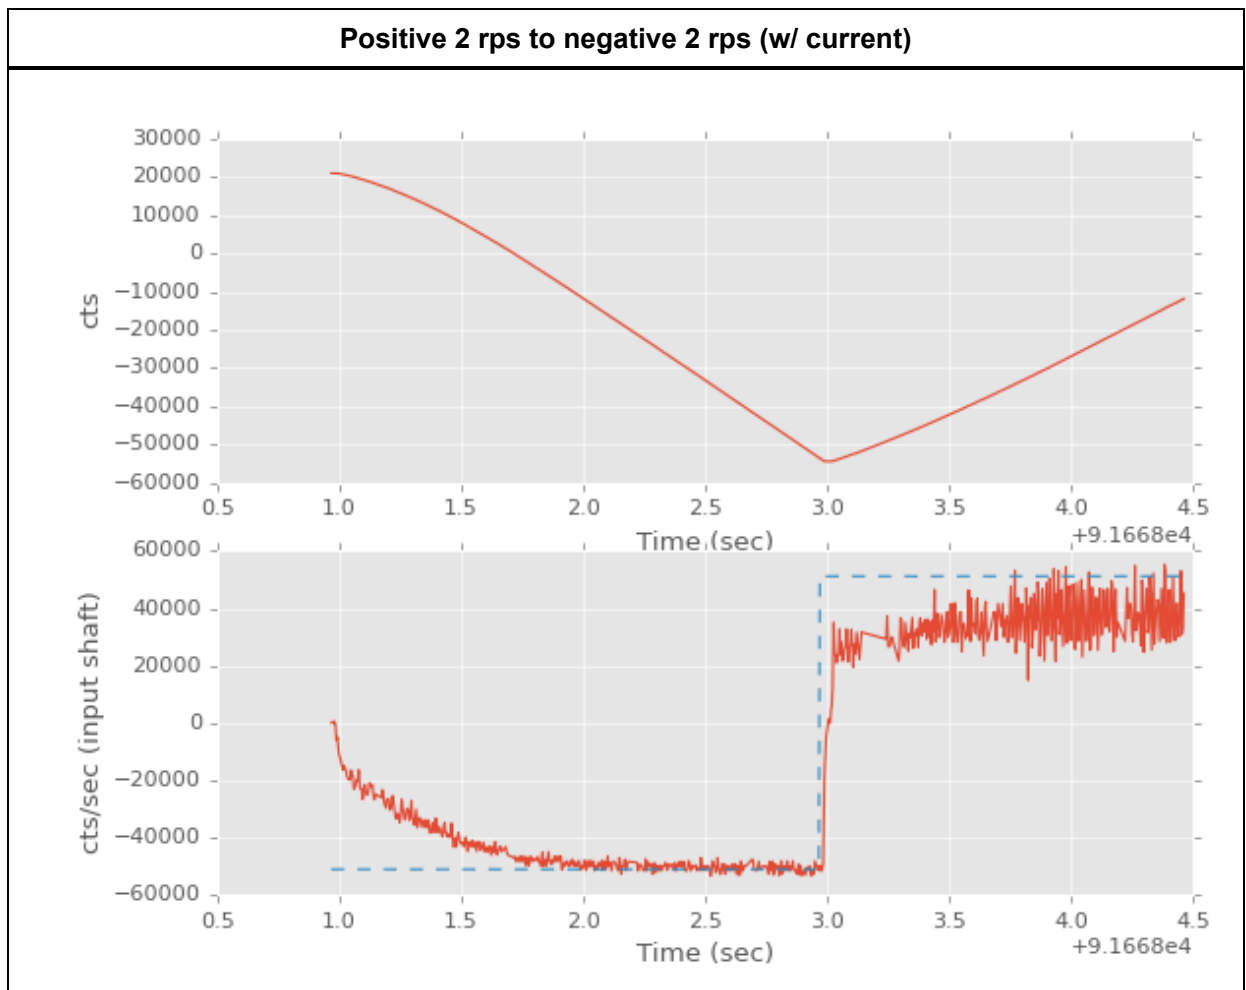

Similar results for .1 rps and 2 rps (both w/ current)

**Positive .1 rps to negative .1 rps (w/ current)****Positive 2 rps to negative 2 rps (w/ current)**

## Conclusions

1. There are some issues with the encoder ticks and the encoder noise in general. This is most noticeable at 0 and low velocities. This is likely related to some of the control problems we see in position mode or when running a position controller since a lot of time can be spent in this regime when holding position.
2. There is some asymmetry between positive and negative going velocities.
3. Velocity following error
